1. Introduction
Myiasis is a parasitic infestation of the body by fly larvae. The common hosts of this larva are the animals, but in some cases it can also affect the human, which is rarely reported in children and commonly found in tropical and developing countries.

Case Presentation: This study, presents a case of cutaneous myiasis in an infant. A 11-month-old girl with popular lesion on buccal area, she does not response to the initial anti-bacterial therapies and progress the buccal cellulitis. Retrieval of three larvae from the lesion led to definitive diagnosis of Calliphora vicina (Diptera: Calliphoridae) larvae infestation and treatment by occlusive ointment, resulted in complete cure.

Conclusions: The myiasis is an uncommon disease in Iran and physicians should be aware of this disease, especially if there are non-healing lesions on exposed skin and worm-like protruding lesion.

Keywords: Myasis; Cellulitis; Calliphoravicina; Child; Iran

2. Case Presentation
A healthy 11-month-old girl was referred to Besat General Hospital, in Hamadan city with buccal swelling and erythema, which has been appeared three days before (Figure 1). Her mother complained of movements inside the affected area and egress of worm-like organisms from the whole affected area. Physical examinations showed a single nodule were indurated erythematous (diameter 1.5 cm) and a central pore (diameter 3 mm) containing three moving larvae. Except low grade fever (38.4 °C), she did not have any other systemic symptoms. After applying the occlusive ointment, the larvae moved out next day without any intervention. The larvae were 13*50 mm, 80*20 mm and 50*10 mm in size (Figure 2).

Two of the dead larvae were in third and fourth stages post mortality, which have been observed by Pouri solution (Figure 3).

The cephalo-pharyngeal skeleton and both anterior and posterior spiracles dissected and mounted on glass slide by Pouri solution (Figure 2).

Implication for health policy/practice/research/medical education:
The myiasis is a rare disease, which its diagnosis requires awareness and high clinical suspicion but physicians should have knowledge about this condition in children.

After desiccation the larva was keyed using valid characteristic keys (1, 16, 17). The morphological features of the larvae were characterized as *Calliphora vicina* Robineau-Desvoidy 1830 (Diptera: Calliphoridae) (18-20). Since both larvae were dead, identification was done according to the larvae characters and results were reported to the hospital. The final diagnosis was cutaneous myiasis. She had been visited by three physicians before referring to our hospital, but this diagnose was different with their differential diagnosis. After removing the larvae using an occlusive ointment, buccal cellulitis was treated with systemic antibiotic and the patient fully recovered within a few days.

3. Conclusions

*Calliphora vicina* (Calliphoridae) known as the bluebottle flies, due to its metallic blue-gray color of thorax and abdomen is a cosmopolitan species in 13-24 °C (55 - 75 °F) urban and natural environments, mainly in spring and fall. In Iran, this species has been reported from Tehran and the suburb (20). This fly is usually closely associated with man. Human myiasis usually occurs accidentally in neglected wounds and suppurating or necrotic tissues and it has a lower threshold temperature for flight activity compared to the other blowflies, which allows a greater prevalence during colder periods. Climatic factors such as temperature are also known to influence the egg laying and development of instar larvae. In warmer climate, the lifecycle span is shorter, and in cooler temperatures the lifecycle is longer (20).

The initial misdiagnosis and delayed appropriate treatment caused unnecessary distress for the patients. Accurate diagnosis of cutaneous myiasis requires knowledge about the disease, patients’ exposure history and clinical suspicion. Main feature for cutaneous myiasis includes one or more non healing lesions on exposed skin and a few mm to 2 cm erythema; some serous, serosanguineaus or seropurulent drainage from a central pore. Local symptoms including pain, tenderness, purities or movement...
inside the lesion are so important. Sometimes worm-like protruding lesions are observed when pressed laterally. Definitive diagnosis is achieved after extraction and identification of the fly larvae. The myiasis is an uncommon disease in our country, whose diagnosis requires awareness and high clinical suspicion. Hence, it is important to know that the etiology of this disease is not eradicated and general physician, pediatrician and dermatologists should have knowledge about this very rare condition in children.
