Introduction

Over the last decade, lasers have been accepted as an alternative to traditional methods in surgery. This is due to the fact that many procedures can be performed more efficiently and with less morbidity using lasers as compared with scalps. A wide range of benign oral lesions exists as either an isolated oral finding or the manifestation of dermatologic conditions. These lesions can be removed by different surgical procedures such as the conventional scalpel, electrosurgical scalpel, or lasers. Lasers have beneficial and safe clinical applications for oral medicine specialists in both diagnosis and treatment of different forms of oral mucosal lesions. Some of these applications include the treatment of facial pigmentation or vascular lesions, the excisional biopsy of oral lesions, frenectomy, epulis fissuratum, fibroma, gingival enlargements, gingivectomies, and certain crown lengthening procedures. In addition, surgery by the laser has become a reliable treatment option for oral mucosal lesions. Lasers that are frequently used in the oral surgical processes are Er:YAG (erbium-doped yttrium aluminium garnet laser), carbon dioxide (CO2), KTM Nd:YAG (neodymium-doped yttrium aluminium garnet), and diode, and are considered as an efficient alternative to traditional methods in surgery.
Excision of Oral Benign Exophytic Lesions With a Diode Laser

instrument for some procedures within this specialty.\textsuperscript{10,11}

We could consider a laser as a minimally invasive technique with many advantages such as remote application, better visibility in the surgical field, precise cutting, hemostasis, minor cicatrization, better infection control, excellent wound healing, reduced postoperative pain and swelling, and patient acceptance.\textsuperscript{8,11,12}

In this study, we report the removal of a benign exophytic lesion from the oral cavity by a laser to emphasize the features of this technique and assess its consequences on living tissues.

Case 1

A 26-year-old pregnant woman in the third trimester was referred to the department of oral and maxillofacial diseases, Shahid Beheshti Dental School, with her chief complaint being soft tissue swelling of the anterior maxilla. Clinical examination showed that there was an exophytic smooth surface nodule with a sessile, red-colored, and popular surface near the tooth region, approximately 0.5 cm × 1 cm in dimension. The lesion bled by a little trauma and the patient had poor oral hygiene (Figure 1A). Her past medical history was clear. The lesion was excised completely from its base after local anesthesia injection by a diode laser with an 810 nm continuous wavelength and 3 W power and 300 µm-fiber tips for 180 seconds (Dr. Smile, Italia). The fiber tip got in contact with the lesion during surgery (Figure 1B). Histopathologic evaluations showed pyogenic granuloma as the test result. In this case, the amount of bleeding was far less than expected (Figure 1C).

Case 2

A 56-year-old woman was referred with a complaint of a mass on the cheek for 2 years. Clinical examinations presented an exophytic lesion which was pink, had a smooth surface as well as soft consistency, was 1 cm × 1 cm in dimension, and was located in left buccal mucosa in the line of occlusion (Figure 2A ). There were not any similar lesions on the other sites of the oral cavity. The patient had a history of continuous cheek biting on the same site. Past medical history was normal and the lesion did not have any symptoms. The lesion was excised from its base to the mucosa completely with a diode laser with an 810 nm continuous wavelength and 3 W power and 300 µm-fiber tips for 180 seconds (Dr. Smile, Italia) (Figure 2B). The fiber tip was kept in contact with the lesion during the operation. The histopathologic report was compatible with giant cell fibroma (Figure 2C).

Case 3

A 61-year-old woman presented with a chief complaint of a mass in her mouth. The history of the lesion went back to 2 years ago. She mentioned no history of symptoms such as pain, paresthesia and bleeding, but she said that it gradually enlarged. Intraoral examinations revealed an

Figure 1. (A) An exophytic mass with a smooth and lobulated surface with pink to red color in gingiva. (B) The lesion was excised by a diode laser with an 810 nm wavelength and 3 watt power with minimal bleeding. (C) A mass of highly vascular proliferation is seen. the lesion is covered by parakeratinized stratified squamous epithelium that consistent with pyogenic granuloma.

Figure 2. (A) An exophytic lesion with a smooth surface and a sessile base on the left buccal surface of the mouth. The lesion was excised by a diode laser with an 810nm wavelength and 3W power. (B) One week after the procedure, the site of surgery had a normal healing process with a fibrino-leucocyte pseudo-membrane. (C) A nodular mass composed of dense fibrous connective tissue with collagen bundles in haphazard fashion is seen. The lesion is covered by varying thickness parakeratinized stratified squamous epitheliumThe histopathological view is consistent with giant cell fibroma.
exophytic nodule posterior of the commissure in the left buccal mucosa, approximately 10 mm×10 mm in size. The surface mucosa was hyperkeratotic, with no ulceration (Figure 3A). The mass was sessile and firm in consistency, without any tenderness. The lesion was excised by a diode laser completely with an 810 nm continuous wavelength and 3 W power and 300 µm-fiber tips for 180 seconds (Dr. Smile, Italia) (Figure 3B). The fiber tip had contact with the lesion during surgery. The histopathologic evaluation of the lesion was compatible with irritation fibroma (Figure 3C).

Case 4
A 50-year-old woman was referred with the complaint of a mass in the buccal surface of the posterior section of the mandible. She mentioned that the lesion was present for 3 years prior to the visit.

The systemic review showed no systemic disease. In intraoral examinations, we saw an exophytic sessile lesion with a smooth surface on the left buccal mucosa, along with linea alba approximately 5 mm × 5 mm in size. The consistency of the lesion was soft to firm and its color was similar to the normal mucosa. In medical history, she stated that she bites this area frequently and it interferes with her occlusion. The lesion was completely excised after local anesthesia injection by a diode laser with an 810 nm continuous wavelength and 3 W power and 300 µm-fiber tips for 180 seconds (Dr. Smile, Italia). The fiber tip was in direct contact with the lesion during surgery. This procedure had minimal trauma and bleeding for the patient. Histopathologic characteristic findings were in favor of fibrolipoma (Figure 4C&D).

Case 5
A 34-year-old woman was visited with a chief complaint of a soft tissue mass in the mucosal surface of her lower lip. In the patient history, the lesion had developed from 2 years ago.

The systemic review showed appendectomy surgery 10 years ago. Intraoral examination revealed an exophytic lesion with a smooth and nodular surface on the labial mucosa of the lower lip. The lesion size was approximately 5 mm × 5 mm. The lesion consistency was firm and its color was similar to environmental mucosa (Figure 5A). She mentioned frequent biting of the region. The lesion was excised under local anesthesia by a diode laser with an 810 nm continuous wavelength and 3 W power and 300 µm-fiber tips for 180 seconds (Dr. Smile, Italia). The fiber tip had direct contact with the lesion during surgery (Figure 5B). Follow-up after two weeks showed good healing with a minimal scar. Histopathological investigations revealed that the characteristic of our findings was in favor of irritation fibroma (Figure 5C).

Case 6
A 19-year-old man was referred because of a small mass on the right side of his cheek mucosa. The present illness showed a soft tissue sessile mass in the occlusal line. It had been raised from 1 year ago due to his frequent cheek biting. The lesion was painless. There was no report of systemic disease and drug consumption in his history. It was firm in consistency and the lesion size was 5 mm×

(C) Fibrous connective tissue that covered by hyperplastic stratified squamous epithelium with collagen bundles in haphazard fashion is in favor of fibroma.

**Figure 4.** (A) An exophytic sessile lesion with a smooth surface on the left buccal mucosa, along the occlusal line which was completely excised by a diode laser with an 810 nm continuous wavelength and 3 W power. (B) One month later, clinical follow-up showed complete healing of the tissue. (C&D) Fibrous connective tissue mixed with the lobules of fat cells; this histopathologic view explained fibrolipoma.
Excision of Oral Benign Exophytic Lesions With a Diode Laser

5 mm (Figure 6A). After local anesthesia injection, the lesion was excised completely by a diode laser with an 810 nm continuous wavelength and 3 W power and 300 µm-fiber tips for 180 seconds (Dr. Smile, Italia). The fiber tip was in direct contact with lesions during surgery. One week after the procedure, the site of surgery had a fibro-leucocyttaire pseudo-membrane on the ulcer surface (Figure 6B). Fifteen days after this procedure, the lesion was completely healed. He was instructed about avoiding cheek biting. Histopathologic findings were in favor of irritation fibroma (Figure 6C&D).

Case 7
A 59-year-old edentulous female was consulted by a dentist because of extra tissue in her cheek. Clinical oral examination showed a painless dome-shaped mass in the right buccal mucosa from 3 years prior to the visit. The past medical history revealed rheumatoid arthritis disease controlled with tab/prednisolone, Amp. Methotrexate and tab/folic acid. In oral examinations, a single, sessile, and soft mass was found with the dimensions of 10 mm×10 mm, normal color and a smooth surface (Figure 7A). The lesion was excised under local anesthesia by a diode laser with an 810 nm continuous wavelength and 3 W power and 300 µm-fiber tips for 180 seconds (Dr. Smile, Italia). The fiber tip was in direct contact with the lesion during surgery. The specimen was sent for histopathologic evaluation and its report was in favor of spindle cell lipoma (Figure 7C&D). One week after the lesion removal, we observed a fibro-leucocyttaire membrane on the ulcer surface (Figure 7B), and complete healing of the surgical site took approximately 2 weeks.

Case 8
A 59-year-old man was referred to our department with a painless small mass on the left lip from 1 year ago (Figure 1). In his systemic review, he showed a history of type 2 diabetes mellitus controlled with insulin and metformin. The extraoral examinations revealed a popular lesion with a smooth surface on the left lip commissure. The lesion was sessile and measured about 3 mm × 4 mm in size. The lesion was excised by a diode laser with an 810 nm continuous wavelength and 3 W power and 300 µm-fiber tips for 180 seconds (Dr. Smile, Italia) (Figure 8A

(C & D) presence of lobules of mature fat cells intermixed with spindle cells in a myxoid stroma.
&B). Histopathological examination made the diagnosis as irritation fibroma (Figure 8C).

Case 9
A 50-year-old male patient was referred to the outpatient oral disease department with a chief complaint of a mass on the back of his tongue for the last 10-12 months. In his systemic review, there was a history of cardiac myxoma, surgery on the left ventricle, and coronary artery bypass grafting. He also had a history of high blood pressure controlled with carvedilol, losartan, furosemide, rivaroxaban, digoxin, atorvastatin, and tamsulosin. He also mentioned that the lesion was enlarged gradually as small nontender tissue with a history of bleeding upon irritation. Intra-oral clinical examination revealed an exophytic multilobulated sessile nodule in the 1/3 middle dorsum surface of the tongue, measuring approximately 20 mm x 15 mm in diameter. The mass had firm consistency with no bruit or pulse felt. The overlying mucosa was white and red in color, granular, and showed bleeding with irritation (Figure 9A). The tumor was excised under local anesthesia by a diode laser with an 810 nm continuous wavelength and 3 W power and 300 µm-fiber tips for 180 seconds (Smile, Italia) (Figure 9B). Based on the histopathologic and clinical findings, a provisional diagnosis of squamous papilloma was given (Figure 9C).

Discussion
Many researchers and clinicians believe in improving the efficacy of dental procedures using laser techniques compared with traditional methods in different fields of dentistry.11 Lasers that are routinely used in oral operations include CO2, diode-Er, Nd YAG, as well as low-level lasers for disinfection and accelerating the healing process. Diode lasers have received FDA approval for soft tissue procedures such as incision, ablative excision, and pocket debridement.11,13 The safety and efficacy of diode lasers have been confirmed in the field of minor oral operations, such as removal of irritative lesions, salivary gland and vascular lesions, as well as hyperplastic gingival tissues.14 The advantages of the laser in surgery include improved vision, excellent hemostasis during and after surgery, less swelling, inflammation, and pain at the site of surgery, less scarring, less incision at the surgical site, resulting in less damage to surrounding tissues and in most cases no need for sutures, lower risk of infection, shortened duration of surgery, and thus greater comfort and acceptance for the patient. In addition, there is less need for post medications such as antibiotics and analgesics.8,11,13 The cellular effects of laser energy include heating, protein denaturation, drying, vaporization, and carbonization with all causing the breakdown of biological tissues resulting in the elimination of lesions and tumors from healthy tissues.1 Deep penetration of diode lasers in comparison to other lasers such as CO2, Er,YAG, and Er,Cr:YSGG yields deeper coagulation on the surgical site and releases greater heat acting similar to electrosurgical procedures.11,15,16

In this study, 9 patients had oral exophytic lesions with
a benign nature and different etiologies such as irritative, neoplastic, and viral, which were successfully removed with a diode laser. Interestingly, in these cases reported in this study, lesions were removed with the minimal use of local anesthesia in some cases, especially small cases. The advantages and disadvantages of laser excision in comparison with scalp surgical removal were explained to the patients and then they tended to laser excision. It can be concluded that laser excision can be a useful method for some patients who are afraid of dental injection. Another interesting point in this study was the case of pyogenic granuloma, with an irritant and hemorrhagic nature, where the amount of bleeding during and after the surgery was less than our expectations. This point was also applied to Case No. 9 regarding the size and depth of the lesion. This can be due to deeper coagulation in diode lasers.11

Another important point about these cases was that in 3 cases of our study (Case No. 9–1–7), due to the large defect remaining after the removal of the lesion, a low-Level diode laser with 300 μm-fibre tip, an 810 nm continuous wavelength and 0.3 W power for 30 seconds was applied at the lesion borders to accelerate the healing process, and the results were very satisfying.17 Low-level laser therapy is well tolerated by patients, causes less damage to the surrounding tissues, and provides better healing of the lesions.18

Patients undergoing diode laser surgery for oral lesions appear to feel less pain as the thermal necrosis caused by tissue vaporization covers the sensory nerve endings.19 This was also true about our cases and most patients required or minimally required postoperative analgesia. Nevertheless, numerous clinical trials are required in this regard. Note that surgical removal of the lesions with a diode laser can be performed with minimal or no use of local anesthesia and leads to excellent postoperative healing. Nevertheless, the need for local anesthesia injection depends on the extent of the patient’s pain threshold as well as the size and location of the lesion.1

Conclusion
Efficient and faster soft oral tissue ablation, coagulation, simple application, faster healing, no or minimal pain, no sutures, instant sterilization, little wound shrinkage, minimal surrounding tissue damage, and less need to local anesthesia are the main factors contributing to patient acceptance for laser surgery. Furthermore, it is preferred in the removal of bleeding lesions such as pyogenic granuloma, and for patients with the fear of blade surgery. This technique could be widely practiced in all fields of surgery in the future.

Ethical Considerations
All of the patient provided their written consent, and no identifier information is included in this case series study.

Conflict of Interests
The authors declare no conflict of interest.

Acknowledgments
The authors of this article are grateful to all employees of the Oral and Maxillofacial Department of Shahid Beheshti University of Medical Sciences for their technical support. Also, we would like to thank Sanaz Gholami Tooghchi for her cooperation in preparing histopathologic figures.
